1 Recap: Pseudorandom Generators

- 1. It is possible to construct a hard-core predicate for any one-way function. Let $f:\{0,1\}^* \to \{0,1\}^*$ be any one-way function (or permutation). We define f'(r,x) = (r,f(x)) for |r| = |x|. Then f' is also a one way function (or permutation, respectively), and $h(r,x) = \langle r,x \rangle \mod 2$ is a hard core predicate for f'.
- 2. A pseudorandom generator exists under the assumption that a one-way permutation exists. Formally, if f is a OWP and h is a hard-core predicate for f, then G(s) = (f(s), h(s)) is a PRG with output length $\ell(n) = n + 1$.
- 3. If there exists a PRG G(s) = (f(s), h(s)) with output length $\ell(n) = n + 1$, then

$$G'(s) = (h(s), h(f(s)), h(f^{(2)}(s)), \cdots, h(f^{(m-1)}(s)))$$

is a PRG of output length m for any m = poly(|s|).

While it is well-known that the existence of a PRG implies that a OWF must exist, is the converse also true? That is, does the existence of a one-way function also imply that a pseudorandom generator must exist? In fact, this turns out to be true as well. Hastad, Impagliazzo, Levin, and Luby established in 1989 that a PRG can be constructed from any OWF. Their construction is much more complicated than the one for OWPs, because it must address the issue that the OWF f may be very "unstructured," and thus the distribution of f(x) may be very different from uniform, even when x is uniform. The HILL PRG construction utilizes a random seed of length n^{10} for a OWF of input length n. The details of the construction are beyond the scope of this class.

2 Pseudorandom Functions

2.1 Preliminary Concepts

Having already developed a precise definition for a pseudorandom *string* of bits, a natural extension is, what would a random *function* look like?

A function from $\{0,1\}^n$ to $\{0,1\}$ is given by specifying an output bit for every one of its inputs, of which there are 2^n . Therefore, the set of *all* functions from $\{0,1\}^n$ to $\{0,1\}$ contains exactly 2^{2^n} functions; a "random function" (with this domain and range) is a uniformly choice from this set. Such a function can also be viewed as a uniformly random 2^n -bit string, which simply lists all the function's outputs. However, stated this way, it is impossible to even look at the entire string efficiently (in poly(n) time). Therefore, we define a model in which we give *oracle* access to a function.

Writing \mathcal{A}^f signifies that \mathcal{A} has query access to f, i.e., \mathcal{A} can (adaptively) query the oracle on any input x and receive the output f(x). However, \mathcal{A} only has a "black-box" (input/output) view of f, without any knowledge of how the function f is evaluated.

Definition 2.1 (Oracle indistinguishability). Let $\mathcal{O} = \{O_n\}$ and $\mathcal{O}' = \{O'_n\}$ be ensembles of probability distributions over functions from $\{0,1\}^{\ell_1(n)}$ to $\{0,1\}^{\ell_2(n)}$, for some $\ell_1(n), \ell_2(n) = \operatorname{poly}(n)$. We say that $\mathcal{O} \stackrel{\circ}{\approx} \mathcal{O}'$ if, for all nuppt distinguishers \mathcal{D} ,

$$\mathbf{Adv}_{\mathcal{O},\mathcal{O}'}(\mathcal{D}) := \left| \Pr_{f \leftarrow O_n} [\mathcal{D}^f(1^n) = 1] - \Pr_{f \leftarrow O_n'} [\mathcal{D}^f(1^n) = 1] \right| = \operatorname{negl}(n).$$

Naturally, we say that $\mathcal{O} = \{O_n\}$ is pseudorandom if

$$\mathcal{O} \stackrel{c}{\approx} \Big\{ U\Big(\{0,1\}^{\ell_1(n)} \to \{0,1\}^{\ell_2(n)}\Big) \Big\},\,$$

i.e., if no efficient adversary can distinguish (given only oracle access) between a function sampled according to O_n , and a uniformly random function, with more than negligible advantage.

Definition 2.2 (PRF Family). A family $\left\{f_s: \{0,1\}^{\ell_1(n)} \to \{0,1\}^{\ell_2(n)}\right\}_{s \in \{0,1\}^n}$ is a pseudorandom function family if it is:

- Efficiently computable: there exists a deterministic polynomial-time algorithm F such that $F(s,x) = f_s(x)$ for all $s \in \{0,1\}^n$ and $x \in \{0,1\}^{\ell_1(n)}$.
- Pseudorandom: $\{U(\{f_s\})\}$ is pseudorandom.

Having developed a precise definition of a pseudorandom family of functions, the natural questions arises: Does such a primitive even exist? And under what assumptions?

Notice that if $\ell_1(n) = O(\log n)$, all the outputs values of a function $f: \{0,1\}^{\ell_1(n)} \to \{0,1\}^{\ell_2(n)}$ can be written down as a string of exactly $2^{\ell_1(n)} \cdot \ell_2(n) = \operatorname{poly}(n)$ bits. Moreover, all the function values can be queried in polynomial time, given oracle access. Therefore, a PRF family with $O(\log n)$ -length input may be seen as a PRG, and vice-versa. But do there exist PRF families with longer input lengths — say, n?

2.2 Constructing PRFs

Theorem 2.3. If a pseudorandom generator exists (i.e., if a one-way function exists), then a pseudorandom function family exists for any $\ell_1(n)$, $\ell_2(n) = \text{poly}(n)$.

At first glance, this theorem may seem completely absurd. The number of functions in the family $\{f_s\}$ with a seed length |s|=n is at most 2^n , whereas the total number of functions overall (even with just one-bit outputs) is at least 2^{2^n} . Therefore, our function family is $\approx 2^{-2^n}$ -sparse, i.e., the family $\{f_s\}$ makes up only a doubly exponentially small subset of the entire space of functions.

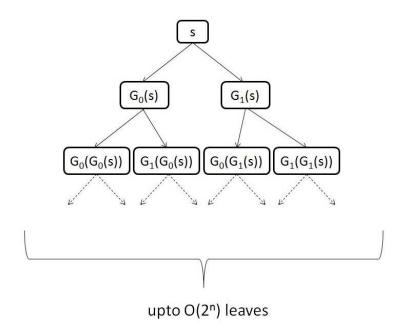

Proof of Theorem 2.3. For simplicity, we prove the theorem for $\ell_1(n) = \ell_2(n) = n$; extending to other values is straightforward.

Our objective is to "stretch" an n-bit uniformly random string to produce an exponential (at least 2^n) number of "random-looking" strings. Assume without loss of generality that G is a PRG with output length $\ell(n)=2n$. The basic idea is to view the output of G as two length-n pseudorandom strings, which can be used recursively as inputs to G to generate an exponential number of strings.

Formally, view G as a pair of length-preserving functions G_0 , G_1 (i.e., $|G_0(s)| = |G_1(s)| = |s|$), where

$$G(s) = G_0(s) \mid G_1(s).$$

The idea behind the PRF construction is that the function $f_s(x)$ computes a path, specified by the bits of x starting from the root seed s, as shown below:

Formally, we define the function $f_s(\cdot)$ as

$$f_s(x) = G_{x_n}(\cdots G_{x_2}(G_{x_1}(s))\cdots).$$

Why might we expect f_s to "look random," for a uniformly random (secret) seed s? Intuitively, $G_0(s)$ and $G_1(s)$ "look like" independent uniform n-bit strings, and we might expect this pseudorandomness to propagate downward through the layers of the tree. Let us try to prove this rigorously.

Attempt 1: Design a sequence of hybrid experiments where each leaf of the tree is successively replaced by its "ideal" form, i.e., with a uniform n-bit string. Clearly, the 0th hybrid corresponds to the "real" tree construction, and the 2^n th corresponds to a truly random function. However, this approach is flawed, as it requires 2^n hybrid steps. (As an exercise, show that the hybrid lemma is false, in general, for an exponential number of hybrid steps.)

Attempt 2: Successively replace each *layer* of the tree with ideal uniform, independent entries (all at once). Thus, H_0 corresponds to the real tree construction, and H_n corresponds to a truly random function. Note that we now have only n hybrid steps.

More formally, we describe hybrid distributions defining (a distribution over functions) f as follows:

- H_0 is the real tree construction, with a uniformly random root s, and $f(x) = G_{x_n}(\cdots G_{x_1}(s)\cdots)$.
- For $i \in [n]$, H_i is the tree construction, but using uniformly random seeds across the *i*th layer of the tree. Formally, $f(x) = G_{x_n}(\cdots G_{x_{i+1}}(s_{x_i\cdots x_1}))$, where the seeds s_y are uniformly random and independent for each $y \in \{0,1\}^i$.

As a warm-up, we first show that $H_0 \stackrel{c}{\approx} H_1$ (in the sense of oracle indistinguishability) assuming that G is a PRG. To prove this, we need to construct a simulator $\mathcal S$ that emulates one of H_0 or H_1 (as oracles), depending on whether its input is $G(U_n)$ or U_{2n} . That is, the simulator should use its input to answer arbitrary queries. The simulator $\mathcal S$ works as follows: given $(z_0,z_1)\in\{0,1\}^{2n}$, it answers each query x by returning $G_{x_n}(\cdots G_{x_2}(z_{x_1})\cdots)$.

It is easy to check that the simulator emulates the desired hybrids. First, if $(z_0, z_1) = (G_0(s), G_1(s))$ for $s \leftarrow U_n$, then $S(z_0, z_1)$ answers each query $x \in \{0, 1\}^n$ as

$$G_{x_n}(\cdots G_{x_2}(G_{x_1}(s))\cdots)=f_s(x),$$

exactly as in H_0 . Similarly, if $(z_0, z_1) \leftarrow (U_n, U_n)$, then S answers each query exactly as in H_1 . Now because $G(U_n) \stackrel{c}{\approx} U_{2n}$ and S is efficient, by the hybrid lemma we conclude that $H_0 \stackrel{c}{\approx} H_1$.

Unfortunately, this approach does not seem to scale too well when we go down to the deeper layers of the tree, because the simulator S would need to take as input an exponential number of input strings. However, we can make two observations:

- In H_i , all the subtrees growing from the *i*th level are *symmetric*, i.e., they are identically distributed and independent.
- The polynomial-time distinguisher \mathcal{D} attacking the PRF can make only a *polynomial* number of queries to its oracle.

The key point is that the simulator then only needs to simulate q(n) = poly(n) number of subtrees in order to answer all the queries of the distinguisher correctly.

For the hybrids H_{i-1} and H_i , Algorithm 2.2 defines a simulator that takes q(n) = poly(n) pairs of n-bit strings.

Algorithm 1 Simulator S_i for emulating either H_{i-1} or H_i .

```
Input: (z_0^1, z_1^1), \dots, (z_0^q, z_1^q) \in \{0, 1\}^{2n} for some large enough q(n) = \text{poly}(n)

1: j \leftarrow 1

2: while there is a query x \in \{0, 1\}^n to answer do

3: if prefix x_1 \cdots x_i is not yet associated with any k then

4: associate j to x_1 \cdots x_i

5: j \leftarrow j + 1

6: end if

7: look up the k associated with prefix x_1 \cdots x_i

8: answer G_{x_n}(\cdots G_{x_{i+1}}(z_{x_i}^k)\cdots)

9: end while
```

We analyze the behavior of S_i . Suppose that the distinguisher \mathcal{D} (making queries to S_i) makes at most q queries, so the counter j never "overflows." Now, if each of the pairs $(z_0^j, z_1^j) \leftarrow G(U_n^j)$ are independent pseudorandom strings, then S_i answers each query x by $G_{x_n}(\cdots(G_{x_{i+1}}(G_{x_i}(U_n^k))\cdots)$, for a distinct k associated uniquely with the i-bit prefix of x. By construction, S_i therefore emulates H_{i-1} exactly. Similarly, if the $(z_0^j, z_1^j) \leftarrow U_{2n}^j$ are uniformly random and independent, then S_i simulates H_i .

At this point, we would like to conclude that $H_{i-1} \stackrel{c}{\approx} H_i$, but can we? To do so using the hybrid lemma, we would need to show that the two types of inputs to S_i (namely, a sequence of q = poly(n) independent pairs (z_0, z_1) each drawn from either $G(U_n)$ or U_{2n}) are indistinguishable. This can be shown via a straightforward hybrid argument, using the hypothesis that G is a PRG, and is left as an exercise. \square

2.3 Consequences for (Un)Learnability

A family of functions is said to be *learnable* if any member of the family can be reconstructed efficiently (i.e., as code), given oracle access to the function. In this sense, a PRF family is *completely unlearnable*, in that

no efficient adversary can determine *anything* about the values of the function (given oracle access) on any of the unqueried points. As a consequence, if a class of functions is expressive enough to "contain" a PRF family, then this class is unlearnable. E.g., under standard assumptions, the class NC¹ can implement PRFs, hence it is unlearnable.
